Abstract: The COVID-19 pandemic has quickly become the most significant public health phenomenon, effectively eclipsing the H1N1 and Ebola crises that came before it. It can spread rapidly and has caused the death and disability of many worldwide. Vaccines are our most effective line of defense against the rapidly spreading and mutating virion. Still, there is significant vaccine hesitancy among those with autoimmune conditions who fear the vaccine may cause them more harm than good. This scoping review explores the safety, outcomes, and effects of COVID-19 vaccines in autoimmune patients. Online databases; Pubmed, Ovid Medline, and Scopus were used to search published literature evaluating the effectiveness and side effects of COVID-19 vaccines in patients with autoimmune conditions. The search results were limited to 4 distinct autoimmune diseases (rheumatoid arthritis, systemic lupus erythematosus, psoriasis, and myasthenia gravis). Thirty-seven studies were retrieved and assessed on the safety, effects, and outcomes of COVID-19 vaccination in patients with the chosen autoimmune conditions. Overall, the risk of flares and the development of severe side effects after vaccination was low. Most autoimmune patients showed a good antibody response to vaccination, especially after the second dose. This review provides a favorable impact of vaccination in patients with autoimmune conditions.

Keywords: COVID-19; vaccines; autoimmune patients; rheumatoid arthritis; systemic lupus erythematosus; psoriasis; myasthenia gravis
1. Introduction

The COVID-19 outbreak, which emerged in China late in 2019, has since quickly spread worldwide to become the most infamous health crisis of our time [1-8]. World Health Organization (WHO) declared COVID-19 a pandemic caused by severe-acute-respiratory-syndrome-coronavirus-2 (SARS-CoV-2) [9-11]. COVID-19 has caused high morbidity and mortality, socioeconomic burden, and pressure on healthcare systems. All these factors can only be reduced by achieving herd immunity against COVID-19 thru vaccination. The virus attacks the host respiratory system and causes flu-like symptoms upon exposure. The disease manifests with a mild respiratory infection, cough, headache, and fatigue at the early stage [12]. Still, as the disease progresses, it may lead to acute respiratory failure with severe complications such as multiorgan failure [13-15]. There is a greater risk of infection among the elderly, patients with autoimmune diseases, and immunocompromised patients [15, 16]. Given the severity of illness in autoimmune patients, clinicians and healthcare professionals have been advocating the importance of being vaccinated.

Pharmaceutical companies raced against time to develop COVID-19 vaccines. The most common COVID-19 vaccine platforms that are currently in use include inactivated virus vaccines (Sinovac, Covaxin, Sinopharm), mRNA (Pfizer-BioNTech and Moderna), and adenovirus vector (AstraZeneca, CanSino, Sputnik V) [17-19]. These vaccines have produced robust humoral responses and presented good outcomes in most vaccinated populations [20]. Vaccinations help to protect the host by creating an antibody response without having the person experience severe illness or post-COVID-19 conditions.

Existing literature suggests that autoimmune patients are at high risk of contracting severe COVID-19 and emphasizes the need for vaccination [21, 22]. However, hesitancy has increased in patients with autoimmune diseases since there is limited data on the safety of COVID-19 vaccines in autoimmune patients. Studies comparing the consequences of different vaccine types between patients and healthy controls are also unavailable [21]. In addition, the disease onset and vaccination can trigger flares. Flares are cumbersome to the patient and would thus discourage them from taking the vaccine; the simple possibility is enough to make them wary of the vaccine roll-out. On top of that, many patients with autoimmune conditions are also on immunosuppressants to keep their conditions at bay. This immunosuppressed state may impair their ability to mount an immune response and even increase their risk of vaccine side effects.

Localized pain on the injection site, fever, body aches, and headaches are among the typical COVID-19 vaccine side effects that people have reported worldwide [23]. Esquivel-Valerio and colleagues studied the impact of six different COVID-19 vaccines on patients with autoimmune rheumatic diseases. They found that localized pain, fatigue, headache, and muscle ache are the most prevalent adverse effects in this group of patients [24]. It is also reported hepatitis B, and influenza vaccines trigger the flares of autoimmune diseases by molecular mimicry inducing autoimmunity [25-27]. This review explores the safety, outcomes, and effects of COVID-19 vaccines in autoimmune patients.
2. Methodology

Three databases (PubMed, Ovid Medline, and Scopus) were searched using search keywords 'rheumatoid arthritis, systemic lupus erythematosus, psoriasis, myasthenia gravis, and COVID-19 vaccines' to retrieve studies evaluating the effectiveness and side effects of COVID-19 vaccines in patients with autoimmune conditions. This review search was focused on four distinct autoimmune diseases (rheumatoid arthritis, systemic lupus erythematosus, psoriasis, and myasthenia gravis). The included studies were published in English between January 2020 and January 2022. Conference proceedings, editorials, dissertations, literature reviews, commentaries, and conference abstracts were excluded. Articles were then screened using Covidence based on the inclusion and exclusion criteria (Table 1).

| Inclusion      | • Studies evaluate the effectiveness and side effects of COVID-19 vaccines in patients with autoimmune diseases.  
                               • Population: Patients with rheumatoid arthritis, systemic lupus erythematosus, psoriasis, and myasthenia gravis. |
| Exclusion      | • Studies related other than COVID-19 vaccines and autoimmune diseases.            
                               • Conference proceedings, commentaries, editorials, dissertations, literature reviews, and conference abstracts. |

3. Results

3.1. Search Results

Three electronic databases were chosen to conduct the search process with search terms. The search retrieved 523 studies from PubMed, Ovid Medline, and Scopus. A total of 204 duplicates were removed from the resulting studies, and 319 articles were kept for the title and abstract screening. Based on the inclusion and exclusion criteria, 59 full-text articles met the eligibility criteria, and 260 articles were excluded. In the end, 37 articles were chosen and included in this review. The scoping review process is shown in Figure 1.
3.2. Characteristics of Included Studies

Of the 37 articles reviewed, the findings were divided into 15 studies on rheumatoid arthritis, 11 studies about psoriasis, seven on systemic lupus erythematosus (SLE), and four on myasthenia gravis.

3.2.1. Rheumatoid arthritis

Of the 15 Rheumatoid arthritis studies, ten evaluated the administration of mRNA vaccines; two discussed mRNA vaccines and viral vector vaccines; one looked at mRNA vaccines and inactivated vaccines; the remaining two explored inactivated either alone or with viral vector vaccines (Table 2). All the study participants were adults (>18 years old). The number of participants varied from 5493 patients in one of the cohort studies to 1 patient in the case report. Spinelli et al. [28] and Geisen et al. [29] found that the vaccine side effects in those with rheumatoid arthritis were similar to those without autoimmune conditions. Local injection site pain was the most common complaint by the patients. Furer and colleagues studied the flare of herpes zoster following BNT162b2 mRNA COVID-19 vaccination in patients with rheumatic diseases. The study found six patients with AIIRD (autoimmune inflammatory rheumatic diseases) developed mild herpes zoster after the first dose of the vaccine and were given oral antiviral therapy with a resolution of herpes zoster symptoms. Five patients completed the second COVID-19 vaccine dose without other
adverse effects. They concluded that further studies are required to assess the safety of the mRNA-based COVID-19 vaccines in patients with AIIRD and the reactivation of zoster \cite{30}.

Seyahi et al. \[42\] CoronaVac (inactivated vaccine) 82 hospital workers with RMD and 300 controls. Rituximab (RTX), DMARDs Among RMD patients, those using immunosuppressive drugs were significantly less likely to have detectable antibodies than those of treatment.

3.2.2. Psoriasis

Of the 11 psoriasis studies, ten focused on mRNA vaccines, and one focused on inactivated vaccines (Table 3). One of the above studies included results from patients taking viral vector vaccines, but no studies focused on that subset of vaccines. Participants were all adults above 18, and the study population ranged from 1 to 436. Five studies focused on the immune response following vaccination, while the remaining 6 explored the risk of exacerbation following anti-COVID-19 vaccination. No studies looked specifically into the side effects of vaccination in psoriatic patients. Generally, the risk of psoriatic flare following vaccination seems very low, but it can happen. Usually, it is not severe and easily managed. The outcomes of vaccination are promising; most patients can mount a detectable immune response even if it is not as significant as that seen in the normal population. Methotrexate has shown itself to reduce the immune response produced by the body.

### 3.3.3. Systemic lupus erythematosus (SLE)

Of the 7 SLE studies, 3 were case reports, 2 were cohort studies, and the remaining two were case series and case-control studies (Table 4). Six studies focused on mRNA vaccines alone, and only 1 study focused on mRNA vaccines and viral vector vaccines. There is a distinct lack of studies looking into the effect of viral vector vaccines and inactivated
vaccines in patients with SLE. The results of the studies looking at vaccination outcomes in patients with SLE were similar to those found in rheumatoid arthritis and psoriasis. Patients with SLE could produce an immune response to the vaccine, but it was weaker than that seen in healthy controls. Assawaksakul et al. [54] added on the potency of the booster in stimulating a stronger immune response and suggested that the viral vector vaccine may not be as effective as the mRNA vaccine in patients with SLE. Regarding disease exacerbations, multiple studies found that the vaccination triggers SLE flares but is not severe enough to warrant hospitalization or emergency care. They have commonly identified side effects of the vaccine, including headache, fatigue, muscle pain, and local injection site pain, similar to that seen in non-autoimmune patients.

3.3.4. Myasthenia gravis

Of the 4 Myasthenia gravis studies, 1 was a single center case series, while the remaining 3 were single case reports (Table 5). The case series was conducted for one month and looked at 22 participants registered on an MG database. All 3 case reports looked at the elderly population (age>60 years old). The participants of the case series ranged from 25 to 73 years old. Three studies looked at the worsening/onset of myasthenia gravis symptoms \cite{61-63}, whereas one looked at the immune response elicited by vaccination \cite{64}. Tagliaferri et al. \cite{62} and Chavez et al. \cite{63} reported a myasthenia gravis crisis in a patient following a second vaccination dose. These two articles suggest that COVID-19 vaccination may be a potential trigger for myasthenia gravis, especially the second dose. Plymate and colleagues showed that immune response was minimal in a myasthenia gravis patient after receiving two doses of the mRNA vaccine, but she then demonstrated an excellent response to the third dose given 85 days later \cite{64}. This suggests that patients with myasthenia gravis may require booster shots to mount an adequate immune response. Ruan et al. \cite{61} reported a retrospective case series demonstrating the safety of inactivated vaccines in patients with myasthenia gravis, defined as mild/absent worsening of symptoms.

4. Discussion

There is a distinct lack of studies focusing on viral vectors and inactivated vaccines in these four different autoimmune disease patients. Each vaccine has a different mechanism of action and, therefore, will have other interactions and effects on the human body, even if they aim to accomplish the same outcome. As such, it isn't easy to conclude the outcomes, safety, and side effects of the vaccines (Figure 2).

Figure 2. The outcome, side-effect and safety of COVID-19 vaccine on autoimmune disease patients.

4.1. Outcomes

Overall, most autoimmune patients can mount a significant immune response to the vaccine even if the potency is less than that of healthy participants. Several studies also seem to show a reduced response after the first dose but a much better response after the following doses. For example, a study by Simander et al. [35], wherein the seroconversion rate after the
first dose was only 54% amongst participants with rheumatoid arthritis as opposed to 98% in the control group, but the seroconversion rates in both groups were 100% after the second dose. A case series by Assawaksakul et al. that looks at 8 SLE patients found a much stronger immune response in patients following a booster dose of the vaccine [54]. The case report by Plymate et al. depicted an older woman who received two doses of the Pfizer/BioNTech vaccine but mounted a negligible immune response following vaccination. She then took a third booster dose 85 days later and showed significant improvement [64]. These studies indicate that patients with autoimmune conditions may benefit more from multiple doses of vaccination than the general population.

As mentioned above, taking Rituximab and DMARDs reduces the immune response in patients with rheumatoid arthritis. Schreiber et al. [40] identified a 32% non-response rate in patients taking DMARDs to manage their arthritis. Picchianti-Diamanti et al. [39] found that suspending the medication during vaccination allowed all patients in their study to develop a strong and sufficient immune response to the vaccine. Patients are taking their medication for a reason. While we want them to get the most out of their vaccination, any decision to stop or modify treatment should be discussed and decided with the advice and guidance of a clinician lest they end up with chronic pain or severe flares.

Rituximab is a form of B-cell-depleting therapy. The study by Madelon et al. found that patients taking Rituximab could still produce good immune responses [38]. Still, the study by Schumacher et al. found that 64% of patients taking Rituximab were vaccine non-responders. Schumacher’s study had a larger population of 102 participants and found a correlation between the antibody response elicited and the interval since Rituximab administration [41]. Interval dosing may allow clinicians to optimize vaccine outcomes without stopping the medication that keeps the patient’s arthritis in remission. However, there is still a small risk of non-response, which should be considered. Since a booster dose seems to offer some benefit in improving outcomes in patients with SLE and myasthenia gravis, it can be considered to optimize vaccine efficacy in patients with Rheumatoid arthritis as well, barring any contraindications.

Prednisone, Janus kinase inhibitors, and Methotrexate hamper the immune response produced by the vaccine, but they don’t seem to cause non-response. As such, it is still beneficial for patients taking these medications to take the anti-COVID-19 vaccine. Venerito et al. find that TNF inhibitors do not impair the vaccine's efficacy [47]. A review by Wack et al. finds that TNF inhibitors may still cause some impairment compared to healthy controls, and therefore the immune response may still be less robust [65]. Interval dosing or suspension of the medication may play a part in all autoimmune patients taking immunosuppressants. Still, the decision should be on a case-by-case basis and with the advice and guidance of a clinician.
4.2. Safety

Myasthenia gravis is an autoimmune neuromuscular junction disorder caused by antibodies to the acetylcholine receptor [66]. It causes fatigable weakness, most evident after repeated muscle use or with the day’s progression. Exacerbations of the condition are usually caused by infection, especially since the advent of this pandemic. Since infection with SARS-CoV-2 can cause a worsening, it warrants the suggestion that vaccination against SARS-CoV-2 could also trigger an exacerbation. Studies suggest vaccination is unlikely to trigger an exacerbation, with only 2 participants reporting slight worsening symptoms that quickly resolved within a few days [61-63]. More studies with bigger sample sizes must be conducted before establishing a solid link between symptom flares and vaccination. There is also a lack of studies looking into different types of vaccines and their potential link to myasthenia gravis exacerbations.

Spinelli et al. studied 126 participants, and five rheumatoid arthritis patients had arthritic flare after vaccination [28]. Thankfully, the flares were self-limiting and resolved within a few days with some symptomatic management. The study by Izmirly et al. looked at the risk of SLE flares and found the risk to be about 11.4%, only 1.3% were severe, and none were so severe that they required hospital care [57]. Huang and Tsai studied 32 unimmunized psoriatic patients and 51 immunized patients. They reported that the immunized group patients presented exacerbations compared to the non-immunized group [44]. The mean Psoriatic Arthritis Severity Index (PASI) score also increased from 3.1 to 8 following vaccination. As such, there is undoubtedly some correlation between the vaccine and autoimmune conditions worsening or fluctuating across the board. Flares can be triggered by various factors, from infections to stress to poor medication adherence. Hence, it is difficult to determine whether a flare has resulted from vaccination, disease progression, or perhaps even a combination.

Overall, we can see that the risk of disease flares post-COVID-19 vaccination is significant. Still, the risk of a flare severe enough to require hospitalization or emergency care remains rare and almost exclusive to the odd case report. Most of the flares are mild and self-limiting. Given the increased risk of morbidity and mortality in patients with comorbidities, it may be better for autoimmune patients to be vaccinated rather than remain unvaccinated. The final decision should be discussed and well-thought-out, considering the patient’s risk factors and disease severity. For patients with mild autoimmune conditions in remission, getting vaccinated is likely the lesser of two evils.

4.3. Side Effects

Herpes zoster virus activation was identified as a potential side effect of vaccination in patients with rheumatoid arthritis by Furer et al. [30]. This study documents six patients who developed their first episode of herpes zoster shortly after vaccination. The prevalence amounted to roughly 1.2% in patients with autoimmune rheumatic conditions as opposed to none in the healthy controls. Herpes Zoster viral activation has been reported in connection
to other vaccines, such as trivalent influenza, hepatitis A, and rabies vaccines. Potential mechanisms that might explain the link between mRNA-COVID-19 vaccination and herpes zoster reactivation are related to the stimulation of innate immunity through toll-like receptors (TLRs) by mRNA-based vaccines. TLR signaling has been implicated during the reactivation of herpesviruses, a process essential for these viruses to maintain themselves in the host. TLRs are much more highly expressed in patients with rheumatic disease compared to the general population. This might be why the prevalence of herpes zoster activation following vaccination is much higher in this group compared to the controls.

Hidaka et al. document a case of Evans Syndrome following COVID-19 vaccination [56]. Evans syndrome, a rare condition characterized by the coexistence of autoimmune hemolytic anemia (AHA) and Idiopathic Thrombocytic Purpura (ITP), is associated with SLE. Interestingly, a case of Evans Syndrome following the influenza vaccine has also been reported. Looking at this, we can conclude that an overactive immune response following vaccination is the most likely trigger causing these SLE patients to progress to Evans Syndrome. It is rare, and there has only been one case so far, but it is worth keeping in mind.

Geisen et al. discussed side effects in vaccinated patients with chronic autoimmune conditions, but the side effects identified are quite similar to those seen in the general population; headache, malaise, body aches, injection site pain, fever, etc. [29]. A few other studies in this review have come to a similar conclusion. As mentioned, there is a lack of studies looking into specific side effects elicited by vaccination in patients with myasthenia gravis and other autoimmune conditions. It would be essential to establish if there are any condition-specific side effects that clinicians should investigate when counseling these patients on vaccination.

5. Conclusions

With COVID-19 vaccines becoming widely available and the pandemic once again proving itself to be more resilient than the pandemics that came before it, clinicians need to be prepared to discuss the risks and benefits of vaccination with their autoimmune patients. Based on the information available, we can deduce that the benefits of vaccination in this population group still outweigh the risks and severe complications are rare if present. Neither an autoimmune condition nor any concurrent treatment is a contraindication for the vaccination, but immunosuppressants have shown to reduce the vaccine's efficacy. This can be countered by interval dosing or temporary suspension of the medication, but these are not solutions that would work for everyone. A third vaccination dose to boost immune response appears safe and effective. The decision should be made after viewing each patient as a whole and considering their needs and wants, the severity of their condition, and any limitations they may have. The decision to be vaccinated should not be rushed, especially if patients are hesitant. Patients should be monitored for any undesirable side effects and be able to return to the hospital if they face any severe adverse events. It is also essential that more studies should be carried on to understand better the safety and efficacy of different vaccines in various autoimmune conditions.
Author Contributions: KSV performed the literature search, critical data analysis, and manuscript writing. LT-TH, JW-FL, PP, and VL provided critical editing and proofreading. LT-TH created the illustrative Figure 2 for the manuscript. VL conceptualized this review writing project.
